DIFFIE-HELLMAN KEY EXCHANGE

Aim: To implement Diffie-Hellman key exchange using C.

Algorithm:
- Step 1: Choose a large prime number P and a primitive root modulo (P), denoted as (G). Both parties agree on these values.
- Step 2: Alice chooses a private key (a), while Bob chooses a private key (b). These private keys are kept secret.
- Step 3: Alice calculates her public key (x) using ($x = G^a \bmod P$), and Bob calculates his public key (y) using ($y = G^b \bmod P$).
- Step 4: Alice sends her public key (x) to Bob, and Bob sends his public key (y) to Alice.
- Step 5: Using the received public keys, Alice computes the secret key (ka) using ($ka = y^a \bmod P$), and Bob computes the secret key (kb) using ($kb = x^b \bmod P$).
- Step 6: Both Alice and Bob now have the same shared secret key.
- Step 7: They can now communicate securely using the shared secret key for encryption and decryption.
- Step 8: The security of the Diffie-Hellman Key Exchange relies on the difficulty of calculating discrete logarithms in finite fields.

Program:
```c
#include <math.h>
#include <stdio.h>

long long int power(long long int a, long long int b, long long int P) {
   if (b == 1)
      return a;
   else
      return (((long long int)pow(a, b)) % P);
}
```

```c
int main() {
    long long int P, G, x, a, y, b, ka, kb;

    P = 26;
    printf("The value of P : %lld\n", P);

    G = 12;
    printf("The value of G : %lld\n\n", G);

    a = 6;
    printf("The private key a for Alice : %lld\n", a);
    x = power(G, a, P);

    b = 4;
    printf("The private key b for Bob : %lld\n\n", b);
    y = power(G, b, P);

    ka = power(y, a, P);
    kb = power(x, b, P);

    printf("Secret key for Alice is : %lld\n", ka);
    printf("Secret Key for Bob is : %lld\n", kb);

    return 0;
}
```

Output:

```
/tmp/Bh1WHSEG7Z.o
The value of P : 26
The value of G : 12

The private key a for Alice : 6
The private key b for Bob : 4

Secret key for Alice is : 14
Secret Key for Bob is : 14

=== Code Execution Successful ===
```

Result:
